Resumen: Este artículo describe la participación del grupo LyS en el tass 2015. En la edición de este año, hemos utilizado una red neuronal denominada long short-term memory para abordar los dos retos propuestos: (1) análisis del sentimiento a nivel global y (2) análisis del sentimiento a nivel de aspectos sobre tuits futbolísticos y de política. El rendimiento obtenido por esta red de aprendizaje profundo es comparado con el de nuestro sistema del año pasado, una regresión logística con una regularización cuadrática. Los resultados experimentales muestran que es necesario incluir estrategias como pre-entrenamiento no supervisado, técnicas específicas para representar palabras como vectores o modificar la arquitectura actual para alcanzar resultados acordes con el estado del arte.

Palabras clave: deep learning, long short-term memory, análisis del sentimiento, Twitter

Abstract: This paper describes the participation of the LyS group at TASS 2015. In this year’s edition, we used a long short-term memory neural network to address the two proposed challenges: (1) sentiment analysis at a global level and (2) aspect-based sentiment analysis on football and political tweets. The performance of this deep learning approach is compared to our last-year model, based on a square-regularized logistic regression. Experimental results show that strategies such as unsupervised pre-training, sentiment-specific word embedding or modifying the current architecture might be needed to achieve state-of-the-art results.

Keywords: deep learning, long short-term memory, sentiment analysis, Twitter

1 Introduction

The 4th edition of the TASS workshop addresses two of the most popular tasks on sentiment analysis (SA), focusing on Spanish tweets: (1) polarity classification at a global level and (2) a simplified version of aspect-based sentiment analysis, where the goal is to predict the polarity of a set of predefined and identified aspects (Villena-Román et al., b).

The challenge of polarity classification has been typically tackled from two different angles: lexicon-based and machine learning (ML) approaches. The first group relies on sentiment dictionaries to detect the subjective words or phrases of the text, and defines lexical- (Brooke, Tofiloski, and Taboada, 2009; Thelwall et al., 2010) or syntactic-based rules (Vilares, Alonso, and Gómez-Rodríguez, 2015c) to deal with phenomena such as negation, intensification or irrealis.

The second group focuses on training classifiers through supervised learning algorithms that are fed a number of features (Pang, Lee, and Vaithyanathan, 2002; Mohammad, Kiritchenko, and Zhu, 2013; Hurtado and Pla, 2014). Although competitive when labelled data is provided, they have shown weakness when interpreting the compositionality of complex phrases (e.g. adversative subordinate clauses). In this respect, some studies have evaluated the impact of syntactic-based features on these supervised learning techniques (Vilares, Alonso, and Gómez-Rodríguez, 2015b; Joshi and Penstein-Rosé, 2009) or other related tasks, such as multitopic detection on tweets (Vilares, Alonso,
and Gómez-Rodríguez, 2015a).

More recently, deep learning (Bengio, 2009) has shown its competitiveness on polarity classification. Bespalov et al. (2011) introduce a word-embedding approach for higher-order n-grams, using a multi-layer perceptron and a linear function as the output layer. Socher et al. (2013) introduce a new deep learning architecture, a Recursive Neural Tensor Network, which improved the state of the art on the Pang and Lee (2005) movie reviews corpus, when trained together with the Stanford Sentiment Treebank. Tang et al. (2014) suggest that currently existing word embedding methods are not adequate for SA, because words with completely different sentiment might appear in similar contexts (e.g. ‘good’ and ‘bad’). They pose an sentiment-specific words embedding (SSWE) model, using a deep learning architecture trained from massive distant-supervised tweets. For Spanish, Monteo-Raéz, García-Cumbreras, and Díaz-Galiano (2014) apply word embedding using Word2Vec (Mikolov et al., 2013), to then use those vectors as features for traditional machine learning techniques.

In this paper we also rely on a deep learning architecture, a long short-term memory (LSTM) recurrent neural network, to solve the challenges of this TASS edition. The results are compared with respect to our model for last year’s edition, a logistic regression approach fed with hand-crafted features.

2 Task1: Sentiment Analysis at a global level

Let \( L = \{l_0, l_1, ..., l_n\} \) be the set of polarity labels and \( A = \{a_0, a_1, ..., a_o\} \) the set of aspects and \( T = \{t_0, t_1, ..., t_m\} \) the set of texts, the aim of the task consists of defining an hypothesis function, \( h : T \rightarrow L \).

To train and evaluate the task, the collection from TASS-2014 (Villena-Román et al., 2015) was used. It contains a training set of 7128 tweets, intended to build and tune the models, and two test sets: (1) a pooling-labelled collection of 60798 tweets and (2) a manually-labelled test set of 1000 tweets. The collection is annotated using two different criteria. The first one considers a set of 6 polarities \( L_6 \): no opinion (NONE), positive (P), strongly positive (P+), negative (N), strongly negative (N+) and mixed (NEU), that are tweets that mix both negative and positive ideas. A simplified version with 4 classes \( L_4 \) is also proposed, where the polarities P+ and N+ are included into P and N, respectively.

In the rest of the paper, we will use \( h_4 \) and \( h_6 \) to refer our prediction models for 4 and 6 classes, respectively.

3 Task2: Sentiment Analysis at the aspect level

Let \( L = \{l_0, l_1, ..., l_n\} \) be the set of polarity labels, \( A = \{a_0, a_1, ..., a_o\} \) the set of aspects and \( T = \{t_0, t_1, ..., t_m\} \) the set of texts, the aim of the task consists of defining an hypothesis function, \( h : A \times T \rightarrow L \). Two different corpora are provided to evaluate this task: a SOCIAL-TV corpus with football tweets (1773 training and 1000 test tweets) and a political corpus (784 training and 500 test tweets), called STOMPOL. Each aspect can be assigned the P, N or NEU polarities \( L_3 \).

The TASS organisation provided both A and the identification of the aspects that appear in each tweet, so the task can be seen as identifying the scope \( s(a, t) \) of an aspect \( a \) in the tweet \( t \in T \), with \( s \) a substring of \( t \) and \( a \in A \), to then predict the polarity using the hypothesis function, \( h_3(s) \rightarrow L_3 \).

To identify the scope we followed a naïve approach: given an aspect \( a \) that appears at position \( i \) in a text, \( t = [w_0, ..., w_{i-1}, a_i, ..., w_{i+k}, ..., w_p] \), we created a snippet of length \( x \) that is considered to be the scope of the aspect. Preliminary experiments on the SOCIAL-TV and the STOMPOL corpus showed that \( x = 4 \) and taking the entire tweet were the best options for each collection, respectively.

4 Supervised sentiment analysis models

Our aim this year was to compare our last-year model to a deep learning architecture that was initially available for binary polarity classification.

4.1 Long Short-Term Memory

Long Short-Term Memory (LSTM) is a recurrent neural network (RNN) proposed by Hochreiter and Schmidhuber (1997). Traditional RNN were born with the objective of being able to store representations of inputs in form of activations, showing temporal capacities and helping to learn short-term dependencies. However, they might suffer from
the problem of *exploding gradients*\(^1\). The **LSTM** tries to solve these problems using a different type of units, called *memory cells*, which can remember a value for an arbitrary period of time.

In this work, we use a model composed of a single **LSTM** and a logistic function as the output layer, which has an available implementation\(^2\) in Theano (Bastien et al., 2012).

To train the model, the tweets were tokenised (Gimpel et al., 2011), lemmatised (Taulé, Martí, and Recasens, 2008), converted to lowercase to reduce sparsity and finally indexed. To train the **LSTM-RNN**, we relied on **ADAM** (Zeiler, 2012), an adaptive learning rate method, using stochastic training (batch size = 16) to speed up the learning process. Experiments with non-stochastic training runs did not show an improvement in terms of accuracy. We empirically explored the size of the word embedding\(^3\) and the number of words to keep in the vocabulary\(^4\), obtaining the best performance using a choice of 128 and 10,000 respectively.

### 4.2 L2 logistic regression

Our last-year edition model relied on the simple and well-known squared-regularised logistic regression (L2-LG), that performed very competitively for all polarity classification tasks. A detailed description of this model can be found in Vileora et al. (2014a), but here we just list the features that were used: *lemmas* (Taulé, Martí, and Recasens, 2008), *psychometric properties* (Pennebaker, Francis, and Booth, 2001) and *subjective lexicons* (Saralegi and San Vicente, 2013). This architecture also obtained robust and competitive performance for English tweets, on SemEval 2014 (Vilares et al., 2014b).

**Penalising neutral tweets**

Previous editions of **TASS** have shown that the performance on **NEU** tweets is much lower than for the rest of the classes (Villena-Román et al., a). This year we proposed a small variation on our L2-LG model: a penalising system for **NEU** tweets to determine the polarities under the \(L_6\) configuration, where: given an \(L_4\) and an \(L_6\) **LG**-classifier and a tweet \(t\), if \(h_6(t) = \text{NEU}\) and \(h_4(t) \neq \text{NEU}\) then \(h_6(t) := h_4(t)\). The results obtained on the test set shown that we obtained an improvement of 1 percentage point with this strategy (from 55.2% to 56.8% that is reported in the Experiments section).

### 5 Experimental results

Table 1 compares our models with the best performing run of the rest of the participants (out of date runs are not included). The performance of our current deep learning model is still far from the top ranking systems, and from our last-year model too, although it worked acceptably under the \(L_6\) manually-labelled test.

Table 2 and 3 show the F1 score for each polarity, for the **LSTM-RNN** and L2-LG models, respectively. The results reflect the lack of capacity of the current LSTM model to learn the minority classes in the training data (P, N+ and **NEU**). In this respect, we plan to explore how balanced corpora and bigger corpora can help diminish this problem.

6 Conclusions and future research

In the 4th edition of TASS 2015, we have tried a long short-term memory neural network to determine the polarity of tweets at the global and aspect levels. The performance of this model has been compared with the performance of our last-year system, based on an L2 logistic regression. Experimental results suggest that we need to explore new architectures and specific word embedding representations to obtain state-of-the-art results on sentiment analysis tasks. In this respect, we believe sentiment-specific word embeddings and other deep learning approaches outperformed again our deep learning proposal.
